plt.xlabel('k-axis')
plt.ylabel('n-axis')
plt.show()

```

### 0.0.4 Interpretation

The brightness of each point reflects the observed probability of success, ranging from certain failure (indigo) to certain success (bright yellow). We can see clearly that there is a phase transition curve.

Under minimal assumptions, Theorem II of the reference paper proves that we always encounter a phase transition when we use the regularized formulation to solve the linear inverse problem

with random measurements. The transition occurs where the number of measurements equals the statistical dimension of the descent cone (please refer to the paper p.8 for the exact expression of descent cone). The shift from failure to success takes place over a range of about  $O(\sqrt{n})$  measurements. There are several reasons that the conclusions of Theorem II are significant. The first implication provides evidence about the minimum amount of information we need before we can use the convex method to solve the linear inverse problem. The second implication tells us that we can solve the inverse problem reliably once we have acquired this quantum of information.
